20. ABSTRACT (Continue on reverse side if necessary and identify by block number) The machine repair and adjustment process is one of the elements which characterizes the operations of a production system. In many cases this maintenance system can be described adequately by analytic models. This report derives some mathematical models which depict the steady-state performance of this service system. All the models are steady-state Markov models of a service system having a finite customer population with multiple, independent servers, each having a service time which is Erlang-distributed.		

20. ABSTRACT (Cont'd)

These models have been useful in verifying the maintenance portion of a stochastic production simulation. Some numerical results from the implementing computer program are presented. Results of different models are compared. Computer programs are provided.

MEMORANDUM REPORT

SUBJECT: Models of a Service System for Production Machine Maintenance

1. Reference:

References are designated by bracketed numbers and are included in the footnotes. The references are also listed.

2. Background

This memorandum reports on work associated with a larger study [1], concerned with the productivity of manufacturing systems. A stochastic simulation, called TANDEMT, was developed for the Ref [1] study. Part of TANDEMT characterizes a maintenance system for adjusting and repairing machines on a production line. To verify this part of the simulation, analytic studies of service systems were performed. The models in this study draw from and extend classical queueing theory, such as in Ref [2]. Whereas the analytic models were used to verify a simulation, their use is not limited to that purpose. It has been found that one can forego the simulation and use only analytic models in designing a machine maintenance system*. Recognizing

[2] Gross, Donald and Harris, Carl, Fundamentals of Queueing Theory, John Wiley and Sons, c. 1974.

* The analytic models are included in a subroutine which can be called from TANDEMT. This arrangement is convenient since these programs share input data. In using the routine for system design, the minimum number of repairmen is selected which satisfies constraints on system performance measures.

the general* importance of analytic models of this sort, I have chosen to present certain derivations and results of interest here.

3. Objectives

One purpose of this memorandum is to derive some results which may be useful in modeling a maintenance system which serves a finite population of machines. Another objective is to present parametric studies using these models. A comparison of results of alternative models will also be made. Of interest to analysts are some numerical approximations.

4. Scope

In the language of queueing theory the (finite) population of machines are "customers" and the repairmen who perform maintenance are the "servers". Similarly, the failures of machines are regarded as demands for service, which if unmet are placed in a "service queue". I will use these terms to suggest that these models are not limited to a production setting. The "system" of interest here is the machine maintenance system, which is characterized by the number of repairmen (or servers) and by the probability distribution of service time. These two factors are the distinguishing elements between models in this memorandum. Note that no distinction is made between types of repairmen. For this application any repairman can render the requisite service. These repairmen are not specialists. Further, they are assumed to work as individuals, rather than in teams.

* Other applications of the models considered here are manifold. Finite queueing models have been used in describing the process by which artillery targets are detected and "served" and in describing the FM communications process in tactical fire control nets.

5. Ordinarily, the random arrival of a "demand" for service is regarded as occurring at a rate equal to the product of a unit rate times the number of customers outside* the service system. The time-to-next-demand is conditionally an exponential random variable. For most mature manufacturing systems operating in steady-state, this is a valid description of demand for maintenance. This demand description is used in all models in this report. Actual maintenance experience often shows that the time to complete a maintenance action (time to repair) is a lognormal random variable. To describe a lognormally distributed event in terms of Markov processes involves approximation. For service times which have a coefficient of variation near unity, an exponential approximation is used. However, if the standard deviation of service time is significantly smaller than the mean--as is often the case--an Erlang distribution can be used to describe the service time. The Erlang distribution, or gamma distribution with integer shape parameter p can be represented as the distribution of a sum of p random variables each of which is exponential. For example, in the case of an Erlang distribution with shape parameter 2 and mean \bar{x} , an equivalent stochastic model consists of two serial elements both of which are exponential with common mean $\bar{x}/2$. Generally, the coefficient of variation of a gamma distribution with shape parameter p is $1/\sqrt{p}$. Thus, if the standard deviation of service time is about 0.7 times the mean, an Erlang distribution with shape parameter 2 would be an appropriate statistical model. The models considered here have either exponential or gamma(2) service times.

6. Birth-Death Processes

Consider a service system having a single server whose service times are gamma(2) i.e., are random variables from a gamma probability distribution with shape parameter 2. This is sometimes written $\Gamma(2)$. Let the customer population be m machines. Thus, at most m machines may reside in the maintenance system with at most $m-1$ in the queue. Machine failures occur at inter-event times which are exponential with a rate $(m-k)\lambda$, where k machines are in the system and where

* The term "inside the system" refers to residence in either the service queue or in a service channel being served. After being served a customer leaves the system and is then "outside the system".

the unit rate λ is the unit rate of entry or "birth" rate for a machine into the system. Notationally, let MTBF be the mean time between failures for the population of machines.* Then,

$$\lambda = 1/\text{MTBF}. \quad (1)$$

To model the gamma(2) service times, two stages of service are assumed, each of which is exponentially distributed with rate parameter μ . After the second stage of service is completed the machine leaves the maintenance system. Thus, if μ_1 is the rate of exodus, or "death" rate, from the system

$$\mu = 2\mu_1. \quad (2)$$

With a mean time to repair MTTR,

$$\mu_1 = 1/\text{MTTR}. \quad (3)$$

7. Definitions of States for a Single-Server System

To characterize the possible states of the system, define and number event E_j as follows:

$$E_j = 2j-1, \quad j \geq 1, \quad (4a)$$

with $j-1$ customers in the queue, where the customer being served is in the first stage of service; and

$$E_j = 2j, \quad (4b)$$

with $j-1$ customers in the queue, where the customer being served is in the second stage of service. E_0 denotes the null state. Notationally, let

$$p_n(t) = P\{\text{system is in state } E_n \text{ at time } t\}, \quad 0 \leq n \leq 2m. \quad (5)$$

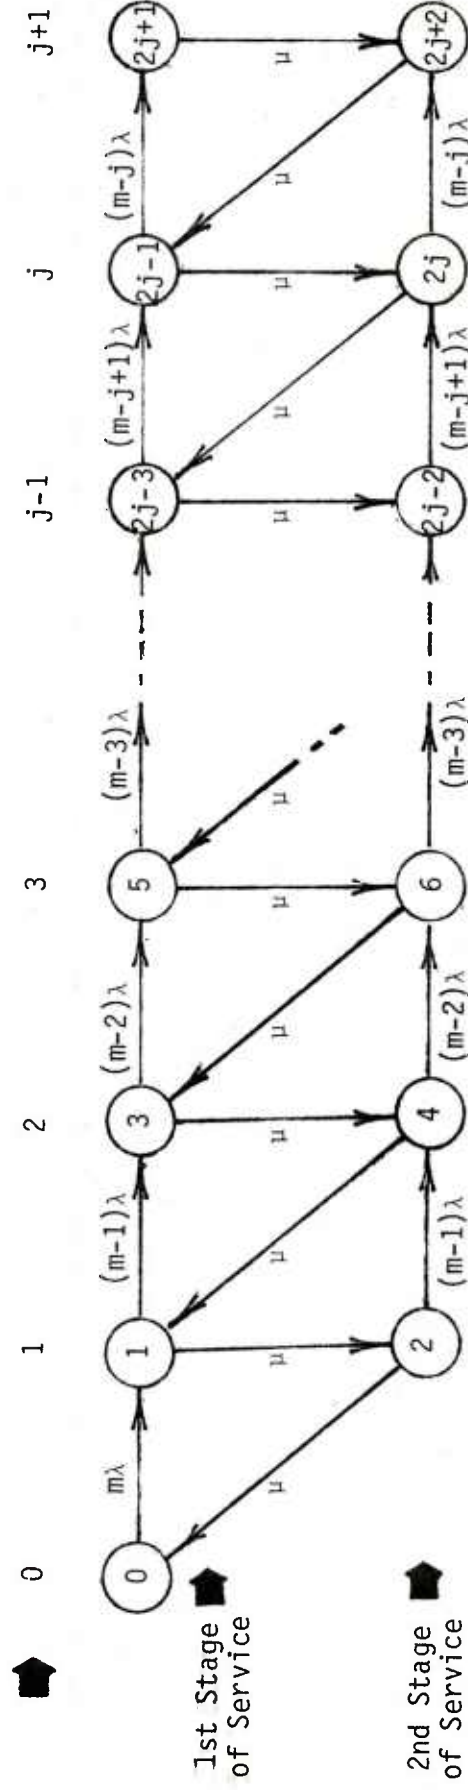

The object of the following derivation is to show how $p_n(t)$ is obtained, for the admissible values of n , when time becomes large, i.e., when the system is in stochastic steady state.

8. State Transitions (Single Server)

It is helpful to examine the ways in which the system can transition between states. Figure 1 displays the states as nodes and the transitions as directed arcs. This state transition diagram also shows the Markov rate constant for

* See Annex B for treatment of a heterogeneous population of machines.

Customers in the System

Definition of States

State E_j is defined by the number of customers in the system and by the stage of service as follows:

$$E_j = 2j-1 \text{ with } j \text{ customers in the system and with the customer being attended in the 1st stage of service.}$$

$$= 2j \text{ with } j \text{ customers in the system and with the customer being attended in the 2nd stage of service,}$$

$$1 \leq j \leq m.$$

Figure 1. State Transition Diagram for a Single-Server Service System With Erlang (2) Service Times

each indicated transition as a label on the arc. Thus, the conditional probability of transition from state 0 to state 1 in an incremental time interval h is $m\lambda h$. Similarly, given the system is in state 1, a transition to state 2 in time increment h occurs with probability μh , and a transition to state 3 in time increment h occurs with probability $(m-1)\lambda h$. Following the standard procedure for Markov processes, one writes the probability of being in state n at time $t+h$ in terms of the probabilities of occupying all of the states at time t . For example,

$$\begin{aligned} P\{E_0 \text{ at } t+h\} &= P\{E_0 \text{ at } t\} \cdot \\ &P\{\text{no transition in } (t, t+h)\} \\ &+ P\{E_2 \text{ at } t\}P\{\text{trans. from } E_2 \text{ to } E_0 \text{ in } (t, t+h)\} . \end{aligned} \quad (6)$$

In our notation,

$$p_0(t+h) = p_0(t) (1 - m\lambda h) + p_2(t)\mu h . \quad (7)$$

Then,

$$\frac{1}{h} [p_0(t+h) - p_0(t)] = -m\lambda p_0(t) + \mu p_2(t) . \quad (8)$$

Taking the limit as h approaches zero yields

$$\dot{p}_0(t) = -m\lambda p_0(t) + \mu p_2(t) . \quad (9)$$

Note that this result can also be obtained by inspection from the state transition diagram. To form the general right hand side: All rates from the k th node are summed; and, the negative of this sum is the coefficient of p_k . All other terms of the r.h.s. have positive coefficients corresponding to the rates on arcs entering the k th node. The j th coefficient multiplies $p_j(t)$, where j is a node leading directly into the k th node.

9. Kolmogorov Equations for a One-Server System

Following the above procedure for all states gives rise to the differential-difference (Kolmogorov) equations which describe this system. Suppressing the notation for time dependence, one has:

$$\dot{p}_0 = -m\lambda p_0 + \mu p_2 .$$

$$\dot{p}_1 = m\lambda p_0 - (\mu + (m-1)\lambda)p_1 + \mu p_4 .$$

For $2 \leq j \leq m-1$,

$$\dot{p}_{2j-1} = (m-j+1)\lambda p_{2j-3} - (\mu + (m-j)\lambda)p_{2j-1} + \mu p_{2j+2}$$

$$\dot{p}_{2j} = (m-j+1)\lambda p_{2j-2} + \mu p_{2j-1} - (\mu + (m-j)\lambda)p_{2j} .$$

And, for the last two states,

$$\dot{p}_{2m-1} = \lambda p_{2m-3} - \mu p_{2m-1}$$

$$\dot{p}_{2m} = \lambda p_{2m-2} + \mu p_{2m-1} - \mu p_{2m} . \quad (10)$$

In stochastic steady state, the time derivatives of all probabilities are zero. Setting dp_k/dt to zero for all k in (10) yields a matrix-vector equation for the state probability vector \underline{p} , with

$$\underline{p}' = (p_1, p_2, \dots, p_{2m}) .$$

The $2m+1$ equations in the set (10) contain one redundant equation since the probabilities are related by

$$p_0 = 1 - \sum_{j=1}^{2m} p_j . \quad (11)$$

One of the equations can be deleted--say, the first--and (11) substituted for p_0 in the second equation (the only other place in which p_0 appears). This process yields

$$-m\lambda \sum_{j=1}^{2m} p_j - (\mu + (m-1)\lambda)p_1 + \mu p_4 = -m\lambda$$

$$(m-1)\lambda p_1 - (\mu + (m-2)\lambda)p_3 + \mu p_6 = 0$$

$$(m-1)\lambda p_2 + \mu p_3 - (\mu + (m-2)\lambda)p_4 = 0 ,$$

and so forth.

The equivalent matrix-vector formulation is

$$A \underline{p} = \underline{b} \quad (12)$$

with A ($2m \times 2m$) and \underline{p} and \underline{b} ($2m \times 1$), where

$$\underline{b}' = (-m\lambda, 0, 0, \dots, 0) , \quad (12b)$$

and

$$A = \{a_{ij}\} . \quad (12c)$$

The elements of A are:

$$a_{11} = -m\lambda - (\mu + (m-1)\lambda)$$

$$a_{1j} = -m\lambda, \quad 2 \leq j \neq 4 \leq 2m$$

$$a_{14} = \mu - m\lambda$$

$$a_{21} = \mu$$

$$a_{22} = -(\mu + (m-1)\lambda)$$

$$a_{2j} = 0, \quad j > 2.$$

For the remaining non-zero terms

$$\text{of } \{a_{ij}\}, \quad 2 \leq k \leq m-1,$$

$$a_{2k-1, 2k-3} = (m-k+1)\lambda$$

$$a_{2k-1, 2k-1} = -(\mu + (m-k)\lambda)$$

$$a_{2k-1, 2k+2} = \mu$$

$$a_{2k, 2k-2} = (m-k+1)\lambda$$

$$a_{2k, 2k-1} = \mu$$

$$a_{2k, 2k} = -(\mu + (m-k)\lambda);$$

$$a_{2m-1, 2m-3} = \lambda$$

$$a_{2m-1, 2m-1} = -\mu$$

$$a_{2m, 2m-2} = \lambda$$

$$a_{2m, 2m-1} = \mu$$

$$a_{2m, 2m} = -\mu.$$

(13)

Since A is of full rank, \underline{p} may be obtained from

$$\underline{p} = A^{-1} \underline{b} . \quad (14)$$

The probability of the null state is obtained from (11).

Then, the probability of the maintenance system having k customers in steady state is given by

$$\pi_k = p_{2k-1} + p_{2k} , \quad 1 \leq k \leq m . \quad (15)$$

10. Statistical Properties of the System

From this probability distribution one obtains the mean and variance* of the number of customers in the system.

$$E[N_{sys}] \equiv \bar{N}_{sys} = \sum_{k=1}^m k \pi_k \quad (16)$$

$$V(N_{sys}) = \sum_{k=1}^m k^2 \pi_k - (\bar{N}_{sys})^2 . \quad (17)$$

The (mathematically) expected number of customers in the queue (\bar{N}_q) is obtained from

$$E[N_q] = \sum_{k=2}^m (k-1) \pi_k$$

or

$$E[N_q] = \bar{N}_{sys} - (1-p_0) \equiv \bar{N}_q \quad (18)$$

The variance of the number in the queue

$$V[N_q] = \sum_{k=2}^m (k-1)^2 \pi_k - (\bar{N}_q)^2 . \quad (19)$$

Related properties are the mean time a customer spends in the system (W) and the mean time spent in the queue (W_q). For all service systems the value of W is greater than W_q by the mean service time. In this case,

$$W = W_q + 1/\mu_1 . \quad (20)$$

* Operator notation is used in displaying the mean and variance. The expectation operator is denoted $E[\cdot]$, and the variance operator $V[\cdot]$.

Given W , equation (20) is used to obtain W_q .

With exponential arrivals and a finite customer population the mean arrival rate is $\lambda(m - \bar{N}_{sys})$. Using this result in Little's formula (p. 120, [2]) yields

$$\bar{N}_{sys} = \lambda(m - \bar{N}_{sys})W ,$$

from which

$$W = \bar{N}_{sys} / [\lambda(m - \bar{N}_{sys})] . \quad (21)$$

Then, W_q can be obtained from (20). Alternatively, W_q is given by another version of Little's formula:

$$W_q = \bar{N}_q / [\lambda(m - \bar{N}_{sys})] . \quad (22)$$

11. Conditional State Probability Distribution

The following derivation is to obtain the probability distributions of waiting time in queue and in the system, given an arriving customer must queue. In doing this, we first obtain the conditional probability distribution that the system is in the n th state, given an arrival. Denote, q_n as the (steady-state) probability that an arrival finds the system in the n th state. From Bayes' theorem, q_n is proportional to the product of two probabilities: (a) $P\{\text{that an arrival occurs, given that the system is in state } n\}$ and (b) $P\{\text{system is in state } n\}$. Thus,

$$\begin{aligned} q_0 &\propto m\lambda p_0 \\ q_1 &\propto (m-1)\lambda p_1 \\ q_2 &\propto (m-1)\lambda p_2 \\ q_3 &\propto (m-2)\lambda p_3 \\ q_4 &\propto (m-2)\lambda p_4 \\ &\vdots \\ q_{2m-3} &\propto (m-1)\lambda p_{2m-3} \\ q_{2m-2} &\propto (m-1)\lambda p_{2m-2} . \end{aligned} \quad (23)$$

[2] Gross, D. and Harris C. Op.Cit., 1974.

Generally, denoting the integer portion of x by $\text{int}[x]$,

$$q_n = (m - \text{int}[(n+1)/2])p_n/K , \quad 0 \leq n \leq 2m-2 , \quad (24)$$

where the normalization constant K is given by

$$K = mp_0 + \sum_{n=1}^{2m-2} (m - \text{int}[(n+1)/2])p_n . \quad (25)$$

The conditional probability density that an arrival finds k other customers in the system is denoted by ρ_k :

$$\begin{aligned} \rho_0 &= q_0 \\ \rho_k &= q_{2k-1} + q_{2k} , \quad 1 \leq k \leq m-1 . \end{aligned} \quad (26)$$

This function is analogous to the unconditional probability density π_k , given by equation (15).

12. Notationally, denote $F_q(t)$ as the distribution of waiting time in queue, T_q :

$$F_q(t) = P\{T_q \leq t\} . \quad (27)$$

The expected value of time in queue from this distribution has been denoted above as W_q . Denote the conditional expectation of time in queue, given a queue as $W_{q|w}$. For a single-server system, queueing occurs whenever the system is not in the null state. Therefore,

$$W_{q|w} = W_q / (1 - q_0) . \quad (28)$$

An alternative -- to equation (22)--means of calculating W_q in this case is the following. This expression is based on the fact--as observed in the state transition diagram (Figure 1)--that an odd state with k customers (E_{2k-1}) involves $2k$ stage transitions of service to leave the system; and, an even state with k customers (E_{2k}) involves $2k-1$ stage transitions of service to leave the system. Each service-stage transition requires an expected time of $1/\mu$. Thus,

$$W_q = \frac{1}{\mu} \sum_{k=1}^{m-1} (2k q_{2k-1} + (2k-1)q_{2k}) . \quad (29)$$

Altho it is not obvious in this case, the mean of waiting time in queue given by (29) equals the value given by the expression (22) from Little's formula. Clearly, equation (22) is preferable computationally; however, development of (22) has motivated the method for deriving $F_q(t)$.

13. Define an integer n^* such that

$$\begin{aligned} n^* &= n+1 & \text{for } n \text{ odd} \\ n^* &= n-1 & \text{for } n \text{ even,} \end{aligned} \quad (30)$$

with n an index over the system states: $1 \leq n \leq 2m-2$.

Then,

$$F_q(t) = q_0 + \sum_{n=1}^{2m-2} q_n P\{n^* \text{ stages of service are completed in time } \leq t, \text{ given an arrival finds the system in the } n \text{ th state}\} . \quad (31)$$

Since each stage of service requires an exponentially-distributed time, with mean μ^{-1} , the time to complete n^* stages has a cumulative distribution which is the n^* -fold convolution of this, namely the gamma cumulative distribution function (c.d.f.):

$$G(n^*, \mu, t) = \int_0^t \frac{\mu (\mu x)^{n^*-1}}{(n^*-1)!} e^{-\mu x} dx . \quad (32)$$

Using (32), one can write (31) as

$$F_q(t) = q_0 + \sum_{n=1}^{2m-1} q_n G(n^*, \mu, t) . \quad (33)$$

With a change in the summation index and using (30), equation (33) becomes

$$F_q(t) = q_0 + \sum_{k=1}^{m-1} (q_{2k-1} G(2k, \mu, t) + q_{2k} G(2k-1, \mu, t)) . \quad (34)$$

A computationally useful form of (34) may be derived using Molina's theorem ([3] and [4], p. 86):

$$\int_0^x \frac{u^{n-1} e^{-u}}{(n-1)!} du = 1 - \sum_{j=0}^{n-1} \frac{x^j e^{-x}}{j!} ; \quad (35a)$$

$$= G(n, 1, x) . \quad (35b)$$

[3] Molina, E.C. Poisson's Exponential Binomial Limit, Van Nostrand, c. 1942.

[4] Schlenker, G. Numerical Methods in Renewal Theory, (AD 828276), Hdqts USA WECOM, February 1968.

Molina's theorem relates a standardized gamma c.d.f. to a sum of Poisson terms. Note that the c.d.f. in (32) with parameters n^* and μ and with argument t is, via a change of variable, equivalent to $G(n^*, 1, \mu t)$. Thus, the gamma c.d.f.'s in (34) can be replaced by the sums required by (35) using an argument x , where

$$x = \mu t . \quad (36)$$

This substitution yields the formula for calculating $F_q(t)$:

$$F_q(t) = 1 - \sum_{k=1}^{m-1} (q_{2k-1} \sum_{j=0}^{2k-1} \frac{x^j e^{-x}}{j!} + q_{2k} \sum_{j=0}^{2k-2} \frac{x^j e^{-x}}{j!}) , \quad (37)$$

or

$$\begin{aligned} F_q(t) &= 1 - q_1 (e^{-x} + x e^{-x}) - q_2 e^{-x} \\ &- e^{-x} \sum_{k=2}^{m-1} (q_{2k-1} \sum_{j=0}^{2k-1} \frac{x^j}{j!} + q_{2k} \sum_{j=0}^{2k-2} \frac{x^j}{j!}) . \end{aligned} \quad (38)$$

This unconditional probability distribution for time in queue can also be used to get the conditional c.d.f., given an arrival must queue. The latter is denoted by $F_{q|w}(t)$. Since q_0 is the probability that an arrival does not need to queue,

$$F_{q|w}(t) = (F_q(t) - q_0) / (1 - q_0) . \quad (39)$$

Using (34) and (39),

$$F_{q|w}(t) = \frac{1}{1 - q_0} \sum_{k=1}^{m-1} (q_{2k-1} G(2k, \mu, t) + q_{2k} G(2k-1, \mu, t)) . \quad (40)$$

Note that the conditional c.d.f. of time in queue is a weighted sum of gamma distributions.

14. Mean and Variance of Conditional Waiting Time in Queue

The j th origin moment of $G(n, \mu, t)$ is given, from p. 33, [4], as

$$a_j = \mu^{-j} \prod_{i=1}^j (n+i-1) . \quad (41)$$

[4] Schlenker, G. Op. Cit.

Specifically, the first and second origin moments are:

$$\begin{aligned} a_1 &= n\mu^{-1} \\ a_2 &= n(n+1)\mu^{-2} . \end{aligned} \quad (42)$$

Using these results, one can obtain expressions for the first and second origin moments for the conditional time in queue ($T_{q|w}$).

From (40),

$$E[T_{q|w}] = \frac{1}{1-q_0} \sum_{k=1}^{m-1} q_{2k-1} 2k\mu^{-1} + q_{2k} (2k-1)\mu^{-1} , \quad (43)$$

and

$$E[T_{q|w}^2] = \frac{1}{1-q_0} \sum_{k=1}^{m-1} q_{2k-1} 2k(2k+1)\mu^{-2} + q_{2k} 2k(2k-1)\mu^{-2} . \quad (44)$$

Then, the variance of the conditional time in queue is obtained from

$$V[T_{q|w}] = E[T_{q|w}^2] - (E[T_{q|w}])^2 . \quad (45)$$

The expression $E[T_{q|w}]$ was earlier denoted by $W_{q|w}$, and was related to W_q by (28). Thus, equation (28) together with (22) provide a consistency check for the value given by (43). This check is performed in the attached computer program FINITE.ME2.Q.

15. Multiple Servers With Exponential Service Times

The formulas derived at this point pertain to the case in which a single server exhibits service times which are Erlang(2). The Kolmogorov equations for this case, tho simple enough, did not lead to a solution of the state probabilities (p_n) in closed form. All equations involved numerical solution with a degree of complexity requiring computer assistance. Another model of a finite-customer population which does lend itself to a somewhat simpler solution is one to which I now turn. In this model the service times are exponential random variables--i.e., Erlang(1) distributed. Further, the number of servers is generalized to an arbitrary integer c . This model has been developed in some detail by Gross and Harris [2]. For this model p_n represents the probability that n customers are found in the service system in stochastic steady state. From p. 118 of Ref [2],

[2] Gross, D. and Harris, C. Op. Cit.

$$p_n = \binom{m}{n} \left(\frac{\lambda}{\mu}\right)^n p_0, \quad 0 \leq n < c \quad (46a)$$

$$p_n = \binom{m}{n} \frac{n!}{c^{n-c} c!} \left(\frac{\lambda}{\mu}\right)^n p_0, \quad c \leq n \leq m. \quad (46b)$$

The value of the probability for the null state is found by setting the sum of the state probabilities to unity.

$$p_0^{-1} = \sum_{n=0}^{c-1} \binom{m}{n} \left(\frac{\lambda}{\mu}\right)^n + \sum_{n=c}^m \binom{m}{n} \frac{n!}{c^{n-c} c!} \left(\frac{\lambda}{\mu}\right)^n. \quad (47)$$

Equations for the mean and variance of the number of customers in the system--analogous to (16) and (17)--are:

$$\bar{N}_{sys} = \sum_{k=1}^m k p_k \quad (48)$$

$$V(N_{sys}) = \sum_{k=1}^m k^2 p_k - (\bar{N}_{sys})^2. \quad (49)$$

Since queueing occurs when $N_{sys} > c$, the expected number of customers in queue is given by

$$\bar{N}_q = \sum_{k=c}^m (k-c) p_k$$

or

$$\bar{N}_q = \bar{N}_{sys} - c + \sum_{k=0}^{c-1} (c-k) p_k. \quad (50)$$

Little's formula is also valid for this model; hence, the mean system waiting time and mean waiting time in queue are given by (21) and (22), respectively.

16. Distribution of Time in Queue (Exponential Services)

The notational conventions used in pgf 11 for the model with Erlang(2) service times are also used here. The conditional probability that an arriving customer finds the system in the n th state is denoted q_n . Bayes' rule requires that

$$q_n = (m-n)p_n / K, \quad (51)$$

where the normalization constant K is found by requiring that

$$\sum_{n=0}^{m-1} q_n = 1.$$

Thus,

$$K = 1 / \sum_{n=0}^{m-1} (m-n)p_n. \quad (52)$$

The following derivation for the c.d.f. of time in queue for a c-server system is a generalization of a result found on p. 125 of [2].

Let $F_q(t)$ be the cumulative (unconditional) distribution of waiting time in queue as in (27). Then,

$$F_q(t) = \sum_{n=c}^{m-1} q_n P\{n-c+1 \text{ job completions occur in time } \leq t, \text{ given an arrival finds } n \text{ in the system}\} + P\{\text{system is open}\}, \quad (53a)$$

where

$$P\{\text{system is open}\} = \sum_{n=0}^{c-1} q_n. \quad (53b)$$

In this model a job completion occurs in exponentially distributed time with rate constant $c\mu$, when the system is full.

Therefore, the

$$P\{n^* \text{ completions occur in time } \leq t\}$$

is given by

$$G(n^*, c\mu, t),$$

with the gamma c.d.f. defined by (32).

Thus,

$$F_q(t) = \sum_{n=c}^{m-1} q_n G(n-c+1, c\mu, t) + \sum_{n=0}^{c-1} q_n. \quad (54)$$

Using Molina's theorem (35), a computationally useful form of (54) is obtained.

$$F_q(t) = 1 - q_c e^{-c\mu t} - e^{-c\mu t} \sum_{n=c+1}^{m-1} q_n \sum_{j=0}^{n-c} \frac{(c\mu t)^j}{j!}. \quad (55)$$

From (54) it is seen that the unconditional expected time in queue is the weighted sum of the means of gamma distributions having different shape parameters. With (42),

$$E[T_q] = \sum_{n=c}^{m-1} q_n (n-c+1)/(c\mu). \quad (56)$$

Similarly,

$$E[T_q^2] = \sum_{n=c}^{m-1} q_n (n-c+1)(n-c+2)/(c\mu)^2. \quad (57)$$

Then, the unconditional variance of time in queue is

$$V(T_q) = E[T_q^2] - (E[T_q])^2. \quad (58)$$

[2] Gross, D. and Harris, C. Op. Cit.

The conditional probability distribution of queueing time, given an arrival must wait, is obtained from $F_q(t)$ by

$$F_{q|w}(t) = (F_q(t) - P\{\text{open}\}) / (1 - P\{\text{open}\}) , \quad (59)$$

where $P\{\text{open}\}$ is given by (53b).

This expression is analogous to (39) for the single-server model.

The first two origin moments of the conditional probability distribution of queueing time are obtained from the corresponding unconditional moments (56, 57) by dividing each by $1 - P\{\text{open}\}$. The variance of this conditional c.d.f. is obtained from the general expression in (45).

17. Numerical Results

Before proceeding with the derivation of other analytic relationships, it is interesting to apply the formulas developed at this point to specific examples. The numerical values chosen are motivated by the author's experience with maintenance of machines for producing metal parts of conventional ammunition. In performing the calculations two computer programs have been useful: FINITE.ME2.Q and BEST.SERVICE. These subprograms are listed in Annex A together with an executive driver. The first program implements the model with conditional Poisson* arrivals and Erlang(2) services. The second program calculates all the statistics for the multiserver model having conditionally Poisson arrivals and exponential services. Both programs treat the population of customers as finite. In order to contrast results from a finite-population model with a model having an infinite customer population, I also evaluate the latter model with an arrival rate parameter (λ_∞) chosen to yield the maximum arrival rate in the finite models. Thus,

$$\lambda_\infty = m\lambda . \quad (60)$$

* Poisson arrivals implies that the time between arriving customers is an exponentially distributed random variable and the arrival rate is a constant parameter. In this case, I mean by "conditionally Poisson" that the arrival rate per customer outside the system is a constant.

The model with infinite customer population which is chosen for comparison with the models of this report has an Erlang(2) service time distribution with a single server. Certain mean-value statistics for this case are presented in [2], starting on page 163. This model is referred to as $(M/E_2/1)$ by Gross and Harris [2].

The expected waiting time-- W_q , in the notation of [2]--for $(M/E_2/1)$ is

$$W_q = \frac{3\lambda_\infty}{4\mu_\infty(\mu_\infty - \lambda_\infty)}$$

where μ_∞ is the stage service rate, denoted elsewhere as μ .

The expected waiting time in the system (W) is given by (20), since this equation is independent of population size. Little's formula yields the expected number in the queue (L_q) and the expected number in the system (L):

$$L_q = \lambda_\infty W_q \quad (62a)$$

$$L = \lambda_\infty W. \quad (62b)$$

The probability that the service system is empty (p_0) is also given in [2]:

$$P\{N=0\} \equiv p_0 = 1 - \lambda_\infty/\mu_\infty. \quad (63)$$

Equations (60) thru (63) were evaluated for comparison with their counterparts of the finite-population models. A numerical comparison of the infinite-population model with the finite population models is made in Table 1. The notational designations for the three models used in Table 1 are Infinite $\Gamma(2)$, Finite $\Gamma(2)$, and Finite Exponential to indicate the customer population size and the service-time distribution function, respectively. The time between arrivals (in minutes) and the number of customers in the population are treated as parameters. One notes that certain output variables agree fairly well across models, such as p_0 , whereas others, such as W_q , do not. Due to the fact that λ_∞ exceeds the average arrival rate in the finite models, the average number in the system and in the queue exceeds their finite-population counterparts. However, it is noteworthy that when the time between arrivals is large (or λ is small) and the customer population is large, the values of $E[N]$ and $E[Q]$ from the infinite model approximate the corresponding values in the finite $\Gamma(2)$ model.

		Wq	15.000	12.868	16.806
		Wq W		27.186	35.809

Notes for Table 1.

(1) The mean time between arrivals per customer is $1/\lambda$. Thus, the maximum arrival rate is λ times the number of customers.

(2) The following notation is used to denote system properties:

$E[N]$	Statistically expected number of customers in the service system.
$SD[N]$	Standard deviation of the number of customers in the service system.
$E[Q]$	Expected value of the number in the service queue.
$P\{N=\emptyset\}$	Probability that the system is empty.
W_q	Expected value of the waiting time (minutes) in the service queue.
$W_q W$	Expected waiting time (minutes) given a customer must queue.

(3) Models are characterized here by the population of customers and by the form of the service-time distribution. Thus, "Inf., $\Gamma(2)$ " signifies an infinite population of customers and a service-time distribution which is gamma (or Erlang) with shape parameter 2. The form of the c.d.f. of time t is

$$F(t) = 1 - (1 + \beta t)e^{-\beta t},$$

with parameter β . The mean of t with this distribution is $2/\beta$.

The other model has a finite customer population and exponentially distributed service times.

18. Comparisons Between Finite Models

The model with exponential service times is computationally much easier than the $\Gamma(2)$ model. Therefore, it is useful to ask for what statistics the models are in reasonable agreement. For these, the model with exponential service will do. Some observations can be made regarding the similarity of results from the finite $\Gamma(2)$ model versus the finite exponential model. Generally, very good agreement exists between these models for the values of $E[N]$, $SD[N]$, and $P\{N=0\}$. Poorer agreement exists for $E[Q]$, and very poor agreement exists for W_q and $W_{q|w}$. Clearly, the difference in dispersion of service times has the greatest effect upon mean waiting time (or conditional mean waiting time). Differences in the conditional waiting time distributions are displayed explicitly in Figures 2 and 3. These figures differ in only one parameter--customer population size. Figures 4 and 5 illustrate the parametric effect of population size for the model with exponential services. Using this model, the parametric effect of number of servers on the c.d.f. of waiting time in queue is shown in Figure 6. These probability distributions are plotted on Weibull probability paper for convenience, since extreme variation in waiting time is shown for any value of a parameter. The following interesting observation can be made from Figure 6. When the number of servers increases--indicating improving service--the conditional distribution function of time in queue closely approximates an exponential distribution. An exponential distribution plots as a straight line on Weibull paper with a slope of unity (Note scale difference of abscissa and ordinate.) Even tho the mathematical form of (55) is clearly not that of an exponential c.d.f., nevertheless an exponential form is a good approximation under certain conditions. After examining a variety of parametric variations with this model, I conclude that a condition under which the exponential approximation is pragmatically adequate is the following: when the mean value of conditional waiting time in queue does not exceed the mean service time. Examples illustrating this point are given in Table 2. The exponential distribution, with single parameter θ , which approximates the conditional c.d.f. of waiting time in queue is denoted by $\tilde{F}(t, \theta)$. The exact c.d.f. is denoted $F(t)$.

$$\tilde{F}(t, \theta) = 1 - \exp(-t/\theta) . \quad (64)$$

196	0.9711	0.9277	0.9393	0.9320	0.9960	0.9951	0.9998	0.9997
280	0.9975	0.9766	0.9677	0.9603	0.9988	0.9983	1.0000	1.0000

* The approximation is an exponential distribution of the form $\bar{F}(t, \theta) = 1 - \exp(-t/\theta)$. The exact distribution is denoted by $F(t)$.

+ Each customer has an exponentially distributed interarrival time. Service times are exponential.

Mean time between interarrivals = 120 minutes/customer.

Customer population = 10.

Mean service time = 20 minutes.

The parameter θ is assigned the exact conditional mean waiting time ($W_{q|w}$). This value can be obtained from easily computed quantities as follows. The system mean waiting time is calculated from (21). Then, W_q is calculated via (20). Both of these relations exploit Little's formula. Then, Bayes' theorem requires

$$W_{q|w} = W_q / (1 - p_q) , \quad (65)$$

where p_q is the probability that an arrival must queue. With c servers,

$$p_q = 1 - \sum_{n=0}^{c-1} q_n . \quad (66)$$

For a single server,

$$q_0 = 1 - p_q \quad (67)$$

$$q_0 = mp_0 / \sum_{n=1}^{m-1} (m-n) p_n . \quad (68)$$

Four pairs of c.d.f.'s are shown in Table 2. The parameter which distinguishes each pair is the number of servers, which varies from 1 to 4. The constants across comparisons are customer population size, mean interarrival time per customer, and mean service time. The mean service time is 20 minutes.

Note that the conditional mean waiting time is less than 20 minutes in the last three comparisons, but not the first. In the first case, with a single server the approximation is poor; whereas, in the other cases the approximation is quite good.

19. Conclusions

The inferences drawn from the numerical examples are summarized here.

- o Unless the activity parameter ($m\lambda/\mu$) is smaller than about 1/3, use of queueing theory for an infinite customer population to describe the behavior of a finite queueing model is quite inexact. Further, there are no compelling numerical reasons for using results applicable to infinite systems.
- o Numerical problems in calculating the system steady-state probability vector were non-existent using double-precision arithmetic on the PRIME 750 minicomputer.
- o If expected values of service system properties such as number of customers in the system and/or in the queue are of primary concern, the differences between finite models having exponential and $r(2)$ service times seem insignificant in practice.

- o One must qualify the previous conclusion. The form of the probability distribution of service time should be selected carefully when the conditional mean time in queue must be accurate. Even with the same mean, different service time c.d.f.'s may yield quite different mean waiting times. This observation holds for exponential versus $r(2)$ service-time distributions.
- o The functional form of the conditional probability distribution of waiting time in queue is generally quite complex. But, a simple approximation exists under certain conditions. For a model with exponential service times, the approximation is valid when the conditional average waiting time in queue does not exceed the mean service time.

20. Recap and Survey of Other Derivations

A review at this point is appropriate. I have discussed two mathematical models used to describe the maintenance system for production machines. Because the population of machines is finite, these queueing models treat a finite customer population. In both cases machine failure is assumed to occur stochastically at a constant rate during machine operation. A failure constitutes the birth of a service demand. Similarly, the completion of service constitutes the death of the service action. With this perspective a Markov birth-death process was used to describe a particular service system probabilistically. This single-server system completes service in a time that has an Erlang(2)-- or $r(2)$ --probability distribution. For contrast, a second model was described which exhibits exponentially distributed service times. The mathematical development of the latter model was nearly complete in the literature on queueing. Only the conditional c.d.f. of waiting time in queue needed to be derived for the multiple-server case. This was done next. Without further mathematical developments, I presented some numerical results. Inferences were made from these results. In the remainder of this memo I will generalize the analytic results of the finite $r(2)$ model to treat several servers. This generalization proceeds in steps. First, two servers are considered. The system state-transition diagram is constructed. From this the Kolmogorov equations are written. Then the method of numerical solution is indicated and certain statistical properties are derived. In deriving these results, equations for the general multiple server case are presented. Finally, a finite $r(2)$ model with three servers is considered. The same procedure for deriving results is followed here as was used for the one- and two-server cases.

21. Two Servers With Erlang(2) Service

The equations derived in paragraphs 6 thru 14 above apply to a service system with a single server. This case was selected initially because of its mathematical simplicity. Frequently, several repairmen work independently and in parallel on machines of (a segment of) a production system. To introduce the treatment of multiple servers, consider the case where 2 servers are present. Each is assumed to have an identical service time distribution which (again) is Erlang(2). The derivation of results follows the pattern used for a single server, with appropriate modification in the definition of system states. In labeling the states of the system, it is convenient to start with a notation which uses double subscripts. Later, the doubly subscripted state variable is replaced with a variable having a single subscript. The procedure followed in this case is easily generalized to cases having more servers. An identical approach was used in an analytic communications model for artillery with CLGP Copperhead (p. 7, [5]).

22. The state of a two-server system is characterized by the number of customers in the system and by the stage of service of each of the servers. The first server is arbitrarily considered to take the first customer. Thus, when only one customer is in the system, the first server is either in the first stage of service or the second, with the other (2nd) server idle. This situation can be represented iconically by the two system configurations:

$$\begin{array}{cc} 0 & 1 & 0 \\ & 0 & 0 \end{array} \quad \text{or} \quad \begin{array}{cc} 0 & 0 & 1 \\ & 0 & 0 \end{array},$$

where the first integer of the first row is the number of customers in queue and where a 1 is placed in the active stage of service for each server.

States are symbolized by the label E_{ij} , where the index i equals the number of customers (k) in the system and the second index j takes on values from 1 to 3 indicating service configuration. All of the state configurations and indices are shown in Table 3.

Figure 7. State Transition Diagram for a Two-Server System with Erlang (2) Service Times

23. Kolmogorov Equations for a Two-Server System

As was done for the single-server system, one can construct a state transition diagram for this system preparatory to writing the Kolmogorov equations. However, the states in this diagram are labeled with the double-index notation. This diagram is shown in Figure 7. We use the same notation for the unit birth rate (λ) into the system and the unit death rate (μ) out of the system. The definitions of λ and μ are given in equations (1) and (3). As assumed earlier, the time between arrivals for customers outside the system is exponential. Since each server is assumed to act independently, the transition rate from the $E_{1,1}$ state to the $E_{1,2}$ state is μ (the stagewise service rate for one server). If both servers worked together, the mean stage service time at this point would be less than μ^{-1} .

24. For this system define

$$P_{ij}(t) = P\{\text{system is in state } E_{ij} \text{ at time } t\} . \quad (69)$$

Then, using the state transition diagram, one can write the Kolmogorov equations by inspection. Notational dependence on time is suppressed. For the non-queueing states,

$$\begin{aligned} \dot{P}_0 &= -m\lambda P_0 + \mu P_{12} \\ \dot{P}_{11} &= m\lambda P_0 - ((m-1)\lambda + \mu)P_{11} + \mu P_{22} \\ \dot{P}_{12} &= \mu P_{11} - ((m-1)\lambda + \mu)P_{12} + 2\mu P_{23} \\ \dot{P}_{21} &= (m-1)\lambda P_{11} - ((m-2)\lambda + 2\mu)P_{21} + \mu P_{32} \\ \dot{P}_{22} &= (m-1)\lambda P_{12} + 2\mu P_{21} - ((m-2)\lambda + 2\mu)P_{22} + 2\mu P_{33} \\ \dot{P}_{23} &= \mu P_{22} - ((m-2)\lambda + 2\mu)P_{23} . \end{aligned} \quad (70)$$

For i customers in the system with

$$\begin{aligned} 3 \leq i \leq m-1 , \\ \dot{P}_{i,1} &= (m-i+1)\lambda P_{i-1,1} - ((m-i)\lambda + 2\mu)P_{i,1} + \mu P_{i+1,2} \\ \dot{P}_{i,2} &= (m-i+1)\lambda P_{i-1,2} + 2\mu P_{i,1} - ((m-i)\lambda + 2\mu)P_{i,2} + 2\mu P_{i+1,3} \\ \dot{P}_{i,3} &= (m-i+1)\lambda P_{i-1,3} + \mu P_{i,2} - ((m-i)\lambda + 2\mu)P_{i,3} . \end{aligned} \quad (71)$$

The last three states are described by

$$\begin{aligned}
 \dot{P}_{m,1} &= \lambda P_{m-1,1} - 2\mu P_{m,1} \\
 \dot{P}_{m,2} &= \lambda P_{m-1,2} + 2\mu P_{m,1} - 2\mu P_{m,2} \\
 \dot{P}_{m,3} &= \lambda P_{m-1,3} + \mu P_{m,2} - 2\mu P_{m,3} .
 \end{aligned} \tag{72}$$

25. Steady-State Equations (Two Servers)

To obtain the steady-state solution to the above equations, all derivatives are set to zero. At this point, the double-subscript notation is changed to a single subscript notation in denoting states. Let the probability of the k th state, in stochastic steady state, be denoted by p_k , so that

$$\begin{aligned}
 p_0 &= P_0(\infty) \\
 p_1 &= P_{11}(\infty) \\
 p_2 &= P_{12}(\infty) \\
 p_3 &= P_{21}(\infty) \\
 p_4 &= P_{22}(\infty) \\
 p_5 &= P_{23}(\infty)
 \end{aligned} \tag{73a}$$

In general, for $2 \leq i \leq m$ and $1 \leq j \leq 3$,

$$k = 3(i-1) + j-1$$

and

$$p_{3i+j-4} = P_{ij}(\infty) . \tag{73b}$$

Note that $\max(k) = 3m-1$.

With this notational change, the steady-state system equations are, from (70, 71, 72, 73),

$$-\lambda p_0 + \mu p_2 = 0$$

$$m\lambda p_0 - ((m-1)\lambda + \mu)p_1 + \mu p_4 = 0$$

$$\mu p_1 - ((m-1)\lambda + \mu)p_2 + 2\mu p_5 = 0$$

$$(m-1)\lambda p_1 - ((m-2)\lambda + 2\mu)p_3 + \mu p_7 = 0$$

$$(m-1)\lambda p_2 + 2\mu p_3 - ((m-2)\lambda + 2\mu)p_4 + 2\mu p_8 = 0$$

$$\mu p_4 - ((m-2)\lambda + 2\mu)p_5 = 0 . \quad (74)$$

Since the probabilities $\{p_k\}$ must sum to unity, the first (redundant) equation in (74) can be discarded and p_0 eliminated from the second via the substitution

$$p_0 = 1 - \sum_{k=1}^{3m-1} p_k . \quad (75)$$

This operation permits the equations for $\{p_k\}$ to be written in matrix-vector form:

$$A \underline{p} = \underline{b} , \quad (76)$$

where

\underline{p} and \underline{b} are $(3m-1 \times 1)$ and A is $(3m-1 \times 3m-1)$.

From the second equation in (74), with (75),

$$a_{11} = -2m\lambda + \lambda - \mu$$

$$a_{14} = \mu - m\lambda$$

$$a_{1j} = -m\lambda , \quad 1 < j < 3m-1 \text{ and } j \neq 4 . \quad (77)$$

Also

$$\underline{b}' = (-m\lambda , 0, 0, \dots, 0) . \quad (78)$$

The elements of $A--\{a_{rc}\}--$ can be assigned in groups of 3 rows each as follows:

For $6 \leq k \leq 3m-4$, corresponding to $3 \leq i \leq m-1$ and $1 \leq j \leq 3$ in the double-subscript notation,

$$\text{let } r = 3(i-1) . \quad (79a)$$

Then,

$$a_{r,3(i-2)} = (m-i+1)\lambda$$

$$a_{r,3(i-1)} = -((m-i)\lambda + 2\mu)$$

$$a_{r,3(i+1)} = \mu . \quad (79b)$$

Now assign

$$\begin{aligned} r &= 3(i-1) + 1 \\ \text{in} \end{aligned} \tag{80a}$$

$$a_{r,3(i-2) + 1} = (m-i+1)\lambda$$

$$a_{r,3(i-1)} = 2\mu$$

$$a_{r,3(i-1) + 1} = -((m-i)\lambda + 2\mu)$$

$$a_{r,3i+2} = 2\mu . \tag{80b}$$

Finally, for

$$r = 3(i-1) + 2 , \tag{81}$$

$$a_{r,3(i-2) + 2} = (m-i+1)\lambda$$

$$a_{r,3(i-1) + 1} = \mu$$

$$a_{r,3(i-1) + 2} = -((m-1)\lambda + 2\mu) . \tag{82}$$

For the last three rows in A,

$$a_{3m-3,3m-6} = \lambda$$

$$a_{3m-3,3m-3} = -2\mu$$

$$a_{3m-2,3m-5} = \lambda$$

$$a_{3m-2,3m-3} = 2\mu$$

$$a_{3m-2,3m-2} = -2\mu$$

$$a_{3m-1,3m-4} = \lambda$$

$$a_{3m-1,3m-2} = \mu$$

$$a_{3m-1,3m-1} = -2\mu . \tag{83}$$

As in the case with a single server, the state probability vector (\underline{p}) is obtained via (14), with \underline{b} and A given in (78) thru (83).

26. Statistics for the Two-Server System

To calculate the mean and variance of number of customers in the system requires aggregation of the system-state probabilities. Recall that π_k is defined as the probability that k customers are in the system. Referring to Table 3 for the definition of states,

$$\begin{aligned}\pi_0 &= p_0 \\ \pi_1 &= p_{11} + p_{12} \\ \pi_k &= \sum_{j=1}^3 p_{kj} \quad , \quad 2 \leq k \leq m .\end{aligned}\tag{84a}$$

Using the single-subscript notation, from (72 and 73),

$$\begin{aligned}\pi_0 &= p_0 \\ \pi_1 &= p_1 + p_2 \\ \pi_k &= p_{3k-3} + p_{3k-2} + p_{3k-1} \quad , \quad 2 \leq k \leq m .\end{aligned}\tag{84b}$$

The mean and variance of number of customers in the system are obtained from (16) and (17). To generalize (84b) for a system with c servers, note that

$$\begin{aligned}\pi_0 &= p_0 \\ \pi_1 &= p_1 + p_2 \\ \pi_2 &= p_3 + p_4 + p_5 \\ &\vdots \\ \pi_{c-1} &= \sum_{j=\ell-c+1}^{\ell} p_j\end{aligned}\tag{85a}$$

with

$$\ell = c(c+1)/2 - 1 .\tag{85b}$$

For $c \leq k \leq m$,

$$\pi_k = \sum_{j=(c+1)k-\ell-1}^{(c+1)k-\ell-1+c} p_j .\tag{85c}$$

With multiple servers, the expected value and variance of the number of busy servers (N_{busy}) are:

$$E[N_{\text{busy}}] = \sum_{k=1}^c k \pi_k + c \sum_{k=c+1}^m \pi_k \quad (86)$$

and

$$V[N_{\text{busy}}] = \sum_{k=1}^c k^2 \pi_k + c^2 \sum_{k=c+1}^m \pi_k - (E[N_{\text{busy}}])^2. \quad (87)$$

With c servers, a queue forms when the number of customers in the system N_{sys} exceeds c . The number in queue

$$N_q = N_{\text{sys}} - c, \quad N_{\text{sys}} \geq c. \quad (88)$$

From this

$$\bar{N}_q = \sum_{k=c+1}^m (k-c) \pi_k \quad (89)$$

and

$$V[N_q] = \sum_{k=c+1}^m (k-c)^2 \pi_k - \bar{N}_q^2. \quad (90)$$

In all these cases Little's formula applies. Hence, the mean waiting time in the system (W) and the mean waiting time in the queue (W_q) are obtained via (21) and (22), respectively.

27. For the specific case of c equal to 2 (with which we are dealing), the conditional state probability density (q_k) is obtained from p_k via a procedure similar to that followed for the single-server case (pgf. 11). In employing Bayes' theorem, states having the same number of customers in the system are grouped. Thus,

$$q_0 = m p_0 / K$$

$$q_1 = (m-1) p_1 / K$$

$$q_2 = (m-1) p_2 / K ;$$

and, in general for $2 \leq k \leq m-1$ and $1 \leq j \leq 3$,

$$q_{3(k-1)+j-1} = K^{-1} (m-k) p_{3(k-1)+j-1}. \quad (91)$$

This set of equations contrasts with (24) for a single server. The constant K is obtained by summing over all states, equating the sum to unity. In the general multiple-server case, the conditional state p.d.f. is obtained from

$$q_0 = mp_0/K$$

$$q_1 = (m-1)p_1/K$$

$$q_2 = (m-1)p_2/K$$

$$q_3 = (m-2)p_3/K$$

$$q_4 = (m-2)p_4/K$$

$$q_5 = (m-2)p_5/K$$

...thru all states with less than c customers in the system. The last such state has index ℓ , where

$$\ell = (c-1)(c+2)/2$$

or

$$\ell = c(c+1)/2 - 1 .$$

Thus,

(92a)

$$q_\ell = (m-c+1)p_\ell/K .$$

(92b)

Additionally, for the states in which the number of customers (k) in the system $\geq c$:

$$q_i = (m-k)p_i/K ,$$

(93a)

with

$$i = (c+1)(k-c) + j + \ell ,$$

(93b)

$$1 \leq j \leq c+1 , \quad c \leq k \leq m-1 .$$

For 2 servers, the conditional probability that an arriving customer finds k others in the system is given by

$$\rho_0 = q_0$$

$$\rho_1 = q_1 + q_2$$

$$\rho_k = \sum_{j=1}^3 q_{3(k-1)+j-1} , \quad 2 \leq k \leq m-1 .$$

(94)

This result corresponds to equation (26) for a single-server system. A generalization of this result to a c-server system is the following:

$$\begin{aligned}
 \rho_0 &= q_0 \\
 \rho_1 &= q_1 + q_2 \\
 \rho_2 &= q_3 + q_4 + q_5 \\
 &\vdots \\
 \rho_{c-1} &= \sum_{j=1}^c q_{\ell-c+j} .
 \end{aligned} \tag{95a}$$

And,

$$\rho_k = \sum_{j=1}^{c+1} q_{(c+1)(k-c)+\ell+j} , \quad c \leq k \leq m-1 . \tag{95b}$$

28. Three Servers With Erlang(2) Service

Derivation of the state equations for the three-server system with Erlang(2) service times follows the pattern used for the two-server system (pgf. 21 ff). To facilitate recognition of states, double subscript notation is also used here. The state E_{ij} signifies that i customers are in the system, with the service stages for the three channels occupied indicated by subscript j . The max value of j is $c+1$ or 4, in this case. These states are depicted iconically and are labeled in Table 4. Note that the last state for which no queueing occurs is $E_{3,4}$. The state transition diagram for this system is shown in Figure 8. As indicated earlier, one can immediately write the Kolmogorov equations by inspection from the state-transition diagram. Parenthetically, the transient version of this model was solved for a communication system having the same transition-state diagram. See p. 14 of [5]. The Kolmogorov equations, in double-subscript notation, yield the time-dependent probabilities $P_{ij}(t)$, for admissible values of i and j . Since the steady-state solution is of interest here, time derivatives are set to zero. Further, the development of a matrix-vector equation for the steady-state probabilities requires conversion to single-subscript notation.

Figure 8. State Transition Diagram for a Three-Server System with Erlang (2) Service Times

29. Steady-State Equations (Three Servers)

The transformation from double to single subscript notation in (73a) is also used for this case. Additionally,

$$p_6 = P_{31}^{(\infty)}$$

$$p_7 = P_{32}^{(\infty)}$$

$$p_8 = P_{33}^{(\infty)}$$

$$p_9 = P_{34}^{(\infty)} .$$

In general, for $3 \leq n \leq m$,

$$p_{4n-6} = P_{n,1}^{(\infty)}$$

$$p_{4n-5} = P_{n,2}^{(\infty)}$$

$$p_{4n-4} = P_{n,3}^{(\infty)}$$

$$p_{4n-3} = P_{n,4}^{(\infty)} .$$

(96)

With these substitutions, the Kolmogorov equations in [5] become:

$$-m\lambda p_0 + \mu p_2 = 0$$

$$m\lambda p_0 - [(m-1)\lambda + \mu]p_1 + \mu p_4 = 0$$

$$\mu p_1 - [(m-1)\lambda + \mu]p_2 + 2\mu p_5 = 0$$

$$(m-1)\lambda p_1 - [(m-2)\lambda + 2\mu]p_3 + \mu p_7 = 0$$

$$(m-1)\lambda p_2 + 2\mu p_3 - [(m-2)\lambda + 2\mu]p_4 + 2\mu p_8 = 0$$

$$\mu p_4 - [(m-2)\lambda + 2\mu]p_5 + 3\mu p_9 = 0$$

$$(m-2)\lambda p_3 - [(m-3)\lambda + 3\mu]p_6 + \mu p_{11} = 0$$

$$(m-2)\lambda p_4 + 3\mu p_6 - [(m-3)\lambda + 3\mu]p_7 + 2\mu p_{12} = 0$$

$$(m-2)\lambda p_5 + 2\mu p_7 - [(m-3)\lambda + 3\mu]p_8 + 3\mu p_{13} = 0$$

$$\mu p_8 - [(m-3)\lambda + 3\mu]p_9 = 0 .$$

For $4 \leq n \leq m-1$,

$$\begin{aligned}
(m-n+1)\lambda p_{4n-10} - [(m-n)\lambda + 3\mu]p_{4n-6} + \mu p_{4n-1} &= 0 \\
(m-n+1)\lambda p_{4n-9} + 3\mu p_{4n-6} - [(m-n)\lambda + 3\mu]p_{4n-5} + 2\mu p_{4n} &= 0 \\
(m-n+1)\lambda p_{4n-8} + 2\mu p_{4n-5} - [(m-n)\lambda + 3\mu]p_{4n-4} + 3\mu p_{4n+1} &= 0 \\
(m-n+1)\lambda p_{4n-7} + \mu p_{4n-4} - [(m-n)\lambda + 3\mu]p_{4n-3} &= 0 .
\end{aligned}$$

The last four states of the system are described by:

$$\begin{aligned}
\lambda p_{4m-10} - 3\mu p_{4m-6} &= 0 \\
\lambda p_{4m-9} + 3\mu p_{4m-6} - 3\mu p_{4m-5} &= 0 \\
\lambda p_{4m-8} + 2\mu p_{4m-5} - 3\mu p_{4m-4} &= 0 \\
\lambda p_{4m-7} + \mu p_{4m-4} - 3\mu p_{4m-3} &= 0 .
\end{aligned} \tag{97}$$

This set of equations contains a redundancy since the state probabilities must sum to unity. To eliminate this redundancy one can substitute

$$p_0 = 1 - \sum_{k=1}^{4m-3} p_k \tag{98}$$

into the first equation in set (97), yielding

$$m\lambda \sum_{k=1}^{4m-3} p_k + \mu p_2 = m\lambda . \tag{99}$$

The second equation in (97), which also involves p_0 , is deleted from the equations to be solved. The final solution set has the following matrix-vector form:

$$A\mathbf{p} = \mathbf{b} , \tag{100a}$$

where \mathbf{p} and \mathbf{b} are $(4m-3 \times 1)$ and A is $(4m-3 \times 4m-3)$.

In this case,

$$\mathbf{b}' = (m\lambda, 0, 0, \dots, 0) . \tag{100b}$$

These equations are analogous to (76), (77), and (78) in the two-server case. In the general c -server case, the dimension of \mathbf{p} is

$$(c+1)m - (c-1)c/2 .$$

30. Statistics for the Three-Server System

Recall that π_k is defined as the probability that k customers are in the system. Elements of the system state probability vector \underline{p} determine the elements of $\underline{\pi}$. The general relationship for a system with c servers is given in (85). Particularizing this for 3 servers,

$$\pi_0 = p_0$$

$$\pi_1 = p_1 + p_2$$

$$\pi_2 = p_2 + p_4 + p_5$$

and, for $3 \leq k \leq m$,

$$\pi_k = \sum_{j=4k-6}^{4k-3} p_j . \quad (101)$$

Other statistics for this case are obtained from their c -server generalizations. Specifically, the mean and variance of busy servers are obtained from (86) and (87). The mean and variance of number of customers in the queue derives from (89) and (90), with mean and variance of number in the system given by (16) and (17). The conditional probability distribution for an arrival finding k other customers in the system is obtained from (95). Since Little's formula holds for a c -server system, the mean waiting time in the system (W) and in the queue (W_q) are obtained from (21) and (22), respectively. For a system with c servers, the probability that an arriving customer must wait in queue is

$$P\{\text{arrival must wait}\} = \sum_{k=c}^{m-1} \rho_k$$

or

$$= 1 - \sum_{k=0}^{c-1} \rho_k . \quad (102)$$

Each of the above statistics is calculated for $c = 1, 2$, or 3 servers in the computer program FINITE.ME2.Q, listed in Annex A.

ANNEX A

COMPUTER SOURCE PROGRAMS

The computer programs in this annex are used to calculate a variety of steady-state statistical properties of queueing systems having a finite customer population and a multi-server service system. Calculations are made for each of two assumptions regarding the probability distribution of service times. The random service time is treated as derived from an Erlang distribution with shape parameter 2 in the program `FINITE.ME2.Q`. The service time is treated as an exponential random variable in the routine `BEST.SERVICE`. Each of these programs call utility routines for inverting and multiplying matrices: `MAT.INVERSE`, `MAT.MPY`, and `MAT.VEC.MPY`. All of these programs are written in SIMSCRIPT 2.5 for the PRIME 750 minicomputer. However, the programs do not employ features unique to this computer. Cross reference lists are included with program statements to facilitate the identification of variable type and to facilitate the location of variables in a program.

A brief (50 lines of executable code) driver program `TEST.FINITE.ME2.Q` reads data interactively from the terminal and echoes these inputs. This program calculates certain queueing statistics for a service system with an infinite population of customers having Poisson arrivals and with Erlang(2) service times. These quantities can be compared with statistics from systems having a finite customer population. The driver program in turn calls `FINITE.ME2.Q` and `BEST.SERVICE`. The first of these programs is largest with 415 lines of executable code. The statistics listed in the program's beginning comments are optionally printed by the routine.

The routine `BEST.SERVICE` has 174 lines of executable code. This program has two calculational modes: one to produce queueing statistics for the parameters supplied and another to sequentially optimize the number of servers, subject to prescribed constraints. In the present application only the calculational mode is invoked.

The major problem segments of all programs are announced via comment statements, which are identified with starting double quote marks. Inputs to the driver program are read from the terminal in response to prompting messages. Output is sent directly to the terminal for display. Since the output is lengthy, it is recommended that a `COMO` file be established to display or print it.

CACI SIMSCKRPT II.5 for PRIME Systems

Options = SEQUENCE,IN,SURCHK,XREF,NOEXPLIST,TRACE3

```

1 ROUTINE FOR BEST SERVICE GIVEN LAMBDA, MU, MPOP, NSERVE, P10LIM, FOLIM, IPRINT,
2 MODE YIELDING, F, NULL, P, SYS, FULL, P, MACH, WAIT, ENO, DOWN, SDNO, DOWN,
3 ENO, QUEUED, ESYS, WAIT, EQ, WAIT, GO, SDQ, WAIT, GO, E, BUSY, SERVERS,
4 SD, BUSY, SERVERS, AND F, NSTATE
5
6 ** AT THE OPTION OF THE USER, THIS ROUTINE ITERATIVELY DETERMINES THE
7 ** MINIMUM NUMBER OF REPAIRMEN (>= NSERVE) REQUIRED TO PROVIDE A GIVEN
8 ** QUALITY OF MAINTENANCE SERVICE. TWO MEASURES OF QUALITY ARE USED:
9 ** (A) THE PROBABILITY THAT THE FRACTION OF MACHINES DOWN EXCEEDS 10%,
10 ** (B) THE EXPECTED FRACTION OF MACHINES QUEUING FOR MAINTENANCE SERVICE.
11 ** AT LEAST ONE OF THESE MEASURES MUST SATISFY ITS ASSOCIATED REQUIREMENT.
12 ** THE STOCHASTIC MODEL ASSUMES EXPONENTIAL TIMES BETWEEN FAILURES AND
13 ** EXPONENTIAL SERVICE TIMES WITH COMMON MTR FOR ALL MACHINES.
14
15 ** INPUT:
16 ** LAMBDA ARRIVAL RATE FOR SERVICE PER INDIVIDUAL MACHINE.
17 ** MU SERVICE RATE PER SERVER.
18 ** MPOP MACHINE POPULATION SIZE.
19 ** NSERVE NUMBER OF SERVICE PERSONNEL.
20 ** P10LIM LIMIT ON PROB THAT 10% OF MACHINES ARE DOWN.
21 ** FOLIM LIMIT ON FRACTION OF THE MACHINES THAT WAIT FOR SERVICE.
22 ** IPRINT INTEGER SWITCH TO PRINT FROM THE SUBROUTINE. PRINTING
23 ** OCCURS WHEN IPRINT=1.
24 ** MODE ROUTINE MODE OF OPN. IF MODE="CALCULATE", STATISTICS
25 ** ARE CALCULATED FOR THE SYSTEM HAVING NSERVE REPAIRMEN.
26 ** NO OTHER SYSTEMS ARE CONSIDERED. IF MODE="OPTIMIZE",
27 ** THE ROUTINE WILL SELECT AN OPTIMUM NUMBER OF REPAIRMEN
28 ** TO SATISFY THE CONSTRAINTS.
29
30 ** OUTPUT: PRINTS THE OPTIMUM NUMBER OF REPAIRMEN (SERVERS) AND THE
31 ** ROUTINE PRINTS PERFORMANCE STATISTICS INCLUDING STATE PROBABILITIES.
32
33 ** ASSOCIATED SYS PERFORMANCE STATISTICS INCLUDING STATE PROBABILITIES.
34
35 ** P, NULL PROBABILITY THE MAINTENANCE SYSTEM IS EMPTY. I.E.,
36 ** P, SYS, FULL PROBABILITY THE MAINTENANCE SYSTEM IS FULL. I.E.,
37 ** THE NUMBER OF CUSTOMERS IN SYS > OR = NSERVE.
38 ** P, MACH, WAIT PROBABILITY THAT AN ARRIVAL FOR MAINT MUST QUEUE.
39 ** ENO, DOWN EXPECTED (MEAN VALUE) NUMBER OF MACHINES DOWN.
40 ** SDNO, DOWN STANDARD DEVIATION OF NUMBER OF MACHINES DOWN.
41 ** ENO, QUEUED EXPECTED NUMBER OF MACHINES IN THE MAINT QUEUE.
42 ** ESYS, WAIT EXPECTED WAIT (MINUTES) IN THE MAINTENANCE SYSTEM.
43 ** EQ, WAIT EXPECTED WAIT (MINUTES) IN THE MAINTENANCE QUEUE.
44 ** SDQ, WAIT GO EXPECTED WAIT, GIVEN A MACHINE MUST WAIT FOR SERVICE.
45 ** L, BUSY, SERVERS STD DEV OF BUSY SERVERS.
46 ** SD, BUSY, SERVERS MEAN NUMBER OF BUSY SERVERS.
47 ** P, NSTATE VECTOR IN WHICH THE N TH ELEMENT IS THE PROBABILITY
48 ** THAT N MACHINES ARE DOWN.
49
50 ** MU, NULL VECTOR IN WHICH THE N TH ELEMENT IS THE PROBABILITY THAT
51 ** AN ARRIVAL FOR SERVICE FINDS THE SYSTEM IN THE N TH STATE.
52 ** PROBABILITY THAT A MACHINE NEEDING SERVICE FINDS THE
53 ** SYSTEM EMPTY.
54
55 ** DEFINE MODE AS A TEXT VARIABLE
56 ** DEFINE I, IPRINT, J, N, MAX, MPOP, N, NSERVE, AND N, TEN, PCT AS INTEGER VARIABLES
57 ** DEFINE P, NSTATE AND GV AS REAL, 1-DIMENSIONAL ARRAYS
58 ** LET RELAND, DA, FC

ANNEX B

HETEROGENEOUS MACHINE POPULATION

The theory presented in the body of this report treats the case of a homogeneous population of machines (customers), whose reliability and maintainability (RAM) parameters are the same for all machines. Thus, equations (1), (2), and (3) do not distinguish between categories or types of machines having possibly different, intrinsic mean times between failure (MTBF) and mean times to repair (MTTR). For this ideal case, the approach presented in the body of the report is exact.

In many instances the population of machines is heterogeneous. In this case an approximation is needed for the RAM parameters which are equivalent to their homogeneous counterparts. This annex discusses an approximation which can be used in conjunction with the previous analytical results to yield queueing statistics which are in good agreement with simulated results for tandem production operations.

On a production line different machine operations may each have several machines of a common type. However, each type of machine (or operation) may have RAM parameters different from parameters of other types. Furthermore, in this setting the machines in a particular operation (n) do not operate continuously. Their failure behavior will reflect this condition. Assuming that the machine operations are asynchronous, a machine must wait: (a) if the downstream buffer is full, (b) if the upstream buffer is empty, or (c) if the machine is down for repairs. The definition of arrival rate per machine (λ) requires the use of the reciprocal of the actual--as opposed to intrinsic--mean clock time between failures. Call this the effective mean time between failures MTBF*. Similarly, the effective mean time to repair (MTTR*) must reflect the diversity of types of machines repaired, the MTTR for each type, and the relative demand for repair by type. Then, the repair parameter (μ_1) used in homogeneous queueing theory is the reciprocal of MTTR*.

The following method is a partial (and imperfect) attempt to account for the non-operating time, in addition to maintenance downtime, which the machines of a particular operation experience. Generally, the production rates of acceptable parts from the machine operations are not identical, i.e., the line

is unbalanced. The machines of an operation which does not have minimal thruput must wait a portion of the time. I define the operational ratio of operation n as the fraction of the average available machine-time which machines at this operation must work in order to meet line thruput. Reference is made to Table B-1 for a complete list of symbols and terms used in this discussion. The average number of machine-minutes actually worked during a day by machines at operation n is, then,

$$U(n)D A(n)\rho(n) , \quad (B-1)$$

where the symbols U , D , A , and ρ are defined in Table B-1. The expected number of maintenance actions required at this operation is this total operating time divided by the $MTBF(n)$. This number is denoted $v(n)$. The total of average daily maintenance actions required is denoted by X .

Formally,

$$X = \sum_{n=1}^N v(n) . \quad (B-2)$$

The total daily average maintenance time required is the following sum over all operations:

$$T = \sum_{n=1}^N v(n)MTTR(n) . \quad (B-3)$$

The effective mean time, per machine, between failures is the maximum daily machine-minutes ($D M$) divided by X :

$$MTBF^* = D M/X . \quad (B-4)$$

The effective mean time to repair is

$$MTTR^* = T/X . \quad (B-5)$$

The equivalent arrival rate of maintenance actions-- $1/MTBF^*$ --is the sum of required actions per unit time over all machine types divided by the total number of machines. The equivalent mean time to repair, or reciprocal equivalent service rate, is a weighted sum of $MTTR$'s for each machine type. The weights in this expression represent the fraction of the total maintenance actions contributed by machines of this (n) type.

At this point the reader may have noticed that one of the outputs of the queueing model (W_q) is needed to define the equivalent values of λ and μ . Availability (A) of machines of a given type in a manufacturing operation is used to estimate the thruput of that operation. This, in turn, is used to develop parameters λ and μ of the queueing model. However, A must consider

the expected waiting time in the maintenance queue (W_q) as well as the intrinsic RAM characteristics of that type of machine. Since A involves W_q , which is not yet known, an iterative solution technique is required. This process starts by assuming that W_q is zero, calculates A for each machine type, which leads to estimates of λ and μ . Use of λ and μ in the queueing model, then, yields an improved estimate of W_q . The better estimate of W_q permits better estimates of λ and μ , and so forth. To accelerate the conversion of this iterative process, it is helpful to use a value of W_q (the same for all machines) which is the average of the i th and $(i-1)$ th iterates. Convergence in some instances is not uniform. Computational experience indicated that truncation of this iterative process occurs rapidly using the following convergence criterion: the relative difference in values of W_q for the last two iterations must be less than 2%. Sound computer coding practice provides a sure escape from the iteration loop after a maximum number of iterations has occurred. In the TANDEMT program, the maximum was set to 20, altho iterative truncation has yet to occur.

TABLE B-1

NOTATION USED IN OBTAINING
EFFECTIVE ARRIVAL AND SERVICE RATES

Symbol	Description
D	length of workday (minutes)
U(n)	the number of (units of) machines of a common type in operation n
N	the number of machine types or machine operations
M	the total number of machine units , $= \sum_n^N U(n)$
MTBF(n)	the mean operating time between failures (minutes) of machines of type n
MTTR(n)	the mean time (minutes) to repair a machine of type n, given maintenance resources
WQ	the mean time (minutes) a machine spends in the repair queue
A(n)	the steady-state availability of machines of type n, $= \text{MTBF}(n) / [\text{MTBF}(n) + \text{MTTR}(n) + \text{WQ}]$
R(n)	unit machine rate (per min) at operation n
AP(n)	average daily production capacity at operation n $= U(n)D R(n)A(n)$
$\alpha(n)$	acceptance rate of parts from machines at operation n only
C(n)	cumulative acceptance rate of parts passing operation n per part starting the first operation $= \prod_{j=1}^n \alpha(j)$
CP(n)	average daily production capacity of <u>acceptable</u> parts at operation n, $= AP(n) \alpha(n)$
n*	value of n for which CP(n) is a minimum $CP(n^*) \leq CP(n) \quad , \quad 1 \leq n \leq N$
RP(n)	average daily parts production at operation n required to meet the average daily line thruput, $= AP(n^*) C(n)/C(n^*)$

TABLE B-1 (Cont'd)

NOTATION USED IN OBTAINING
EFFECTIVE ARRIVAL AND SERVICE RATES

Symbol	Description
$\rho(n)$	operational ratio for machine operation n , $= RP(n)/AP(n)$
$v(n)$	average daily number of maintenance actions for machines of common type in operation n , $= U(n)D A(n)\rho(n)/MTBF(n)$
X	total average daily maintenance actions required, $= \sum_n^N v(n)$
T	total average daily maintenance time (min) required, $= \sum_n^N v(n)MTTR(n)$
$MTBF^*$	effective mean time (min) between failures, $= D M/X$
$MTTR^*$	effective mean time (min) to repair all machines, $= T/X$
λ^*	effective arrival rate (1/minute), $= 1/MTBF^*$
μ_1^*	effective service rate (1/minute), $= 1/MTTR^*$
